The determinants of apprenticeship training with particular reference to business expectations*

Hans Dietrich and Hans-Dieter Gerner**

Whilst in applied empirical research, training in general human capital is mainly explained by structural characteristics of firms, this paper introduces business expectations as an additional explanatory factor. Business expectations are strictly time-variant and firm-specific and reflect both a firm’s development in competitive markets and in the business cycle. We assume that a firm’s business expectations strongly modify the cost-utility concept for firms’ decisions as regards providing apprenticeship places.

When controlling for firms’ structural characteristics, static econometric models support our assumption that a change in business expectations leads to an asymmetric adjustment process of firms’ qualitative decisions regarding apprenticeship training. Concerning the quantitative decision as to how many apprenticeship places a firm provides we found a significant but not asymmetric response to a change in business expectations.

A dynamic approach confirms the results obtained in the static models of a symmetric quantitative adjustment process in a short-term perspective. In a longer perspective the dynamic model supports the assumption of an asymmetric quantitative adjustment process. Further on an application shows that an increasing uncertainty regarding business expectations tends to reduce the apprenticeship training at firm level.

1 Introduction

Since the mid-eighties firms’ provision of apprenticeship places has decreased dramatically in the old German Länder. Whilst in 1986 firms provided some 700,000 new apprenticeship contracts, there were only about 450,000 in 2006. This process has found its continuation in unified Germany since the early nineties. Both sectoral change and the restructuring of enterprises have been identified as the driving mechanisms behind this development. In addition to this structural change, microeconomic studies provide some evidence that firms’ human capital profile, their internal on-the-job training and further training or recruitment strategies and firm-size characteristics explain firms’ provision of apprenticeship places more or less stably over time (Neubäumer/Bellmann 1999; Dietrich 2000; Beckmann 2002; Euwals/Winkelmann 2004; Niederalt 2004; Dietrich/Gerner 2005; Muehlemann et al. 2007).

Besides these firm-specific characteristics of business organisation, recent literature indicates some arguments that uncertainty concerning the further development of business success influences firms’ future provision of new apprenticeship places (DIHK 2006; Bellmann/Hartung 2005). The aim of this paper is to introduce business expectations and uncertainty into microeconomic models explaining firms’ qualitative and quantitative decisions about providing apprenticeship places. According to our considerations, firms’ business expectations reflect both firms’ expected performance in competitive markets and macroeconomic factors such as the expected progress of the business cycle. In this respect business expectations as a core element of firms’ rational decisions are associated with uncertainty in a more general sense. A more specific concept of uncertainty, discussed in more detail in section 5, is adapting a risk concept formulated by Rothschild and Stiglitz (1970).

In the remainder of the paper, on the basis of human capital theory, explanations of firms’ provision of apprenticeship places (Becker 1964; Harhoff/Kane 1997; Acemoglu/Pischke 1998, 1999a and b; Clark/Fahr 2002; Niederalt 2004) are extended by introducing business expectations as an exogenous variable. Compared with more static variables describing firms’ characteristics of organisation and workforce, business expectations seem to be more variable over time. Furthermore we adopt theoretical and empirical considerations about asymmetric processes of adjustment of firms’ training decisions to changes in business expectations.

In the empirical section of this paper we use data from the IAB Establishment Panel. In a first analytical step, a static approach is applied to answer two questions: a) what factors motivate firms to train apprentices (qualitative decision) and b) what happens to the number of apprentices recruited by a firm when these causal factors vary over time (quantitative decision). Subsequently a dynamic approach is used to model the adjustment process for the quantitative decision. In an application we use our results to formulate assumptions about the effect of uncertainty regarding business expectations over time on a firm’s quantitative and qualitative decision as to whether to provide new apprenticeship places in a given year or not.

2 Theoretical considerations

Why do firms pay for apprenticeship training (regulated by the German vocational training act, BBiG), even if apprenticeship training is an investment in general human capital? Becker already raised this question in the early sixties (see Becker 1962; 1964) and Acemoglu/Pischke (1999a, b) and Niederalt (2004) reviewed in detail the ongoing research especially related to the German apprenticeship system.

In particular two types of training costs can be distinguished: direct and indirect costs. Direct costs are for example expenditure on firm-based training facilities or wages for apprentices. Indirect costs occur while workers spend part of their working time on training apprentices instead of on production. A net cost perspective takes into account the fact that even apprentices may be productive while being trained. Calculations by Beicht and Walden (2004) present a remarkable variation of net training costs, explained partly by firm size, industry and the type of occupation that apprentices are being trained in. Concepts motivated by net cost are closely related to assumptions derived from production-theory considerations (see Lindley 1975; Fougère/Scherwrdt 2002; Zwick 2007). Also, a specific type of firm is able to gain net returns from investments in general training already during the training period.

In general, production-motivated explanations are not sufficient to explain firms’ training activities in apprenticeship training. So it is also worth noting that considerations oriented towards net cost only take into account costs and returns occurring during the institutionally defined period of contract-based apprenticeship training. Opportunity costs or transaction costs (e.g. recruitment costs for skilled employees) may occur, however, when this type of training is completed. These types of costs are not considered here. Investment-motivated considera-
tions (Stevens 1994; Franz/Soskice 1995; Timmermann 1998; Fougère/Schwerdt 2002) reflect the returns on training after the completion of an apprenticeship. From this viewpoint, apprenticeship training improves not only productivity during the training period but also future productivity. High mobility costs for workers, institutional barriers and low labour turnover in Germany (Harhoff/Kane 1997), asymmetric information on the ability of the apprentices and other market imperfections generate compressed wage structures and allow firms providing apprenticeship training to take a rent from employees trained within the firm compared with firms who recruit employees on the labour market (Acemoglu/Pischke 1998, 1999a, 1999b; Beckmann 2002; Clark/Fahr 2002). Following Franz/Soskice (1995) and Werwatz (1996) apprenticeship training provides additional firm-specific skills. According to assumptions on high factor specificity (Holtbrügge 2004; Williamson 1990) training firms may have additional advantages from this firm-specific human capital which is generated en-passant.1

Increasing or decreasing business expectations, however, affect both the cost and the reward sides of apprenticeship training. Decreasing business expectations indicate to training firms an expected reduction in the productive contribution of apprentices to the firm. As a consequence the net costs of apprenticeship training may increase and training firms will reduce their provision of training capacities. A precondition for long-term returns on firm-based training is that firms will be able to retain apprentices after the training period. As labour demand depend on the demand for goods (Freemann 1972), the future market position must be sufficient to retain the apprentices who are currently undergoing training. When offering new apprenticeship places, firms have to make their decisions under uncertainty. So business expectations could be a relevant indicator in firms’ decisions. Expanding on Acemoglu/Pischke (1999a, 1999b), a reduction in business expectations should decrease not only the probability of firms retaining their own apprentices afterwards but also the probability of using them productively during the apprenticeship training. As a consequence this will increase the expected net costs of training.

Supported by empirical evidence, assumptions from behavioural finance suggest that a deficit of a given amount is perceived by actors more sorely, than earnings of the same amount increase individual utility – this paradox motivates so-called loss aversion (Bank 2003; Gul 1991). Given a loss-averse behaviour, actors will renounce investments more easily with a given decrease in business expectations than they will make investments in the opposite case. In this respect, firms’ training decisions should correspond with asymmetric investment or adjustment decisions. We assume that firms will reduce their training facility to a greater extent than they would intensify their training facilities in the case that business expectations improved to the same extent.

From a human-capital theory perspective, firms’ training behaviour depends on enterprise-specific characteristics such as the human capital distribution of the employees, recruiting strategy, industry or firm size (Neubäumer/Bellmann 1999; Dietrich 2000; Dietrich/Gerner 2005; Niederalt 2004, 2005; Zwick 2007).

3 Econometric analysis – Part 1: static approach

3.1 Econometric strategy, data, variables and hypothesis

Analytically there are two basic management decisions – first a qualitative decision: either the firm trains apprentices or it does not, and second the quantitative decision: how many apprentices are to be trained by an individual firm (Niederalt 2004, 2005).

To model the qualitative decision, we apply logit techniques. To use the structure of the data, we control for unobserved heterogeneity by estimating both a logit model with random effects (see Conway 1990; Liu/Pierce 1994) and a logit model with fixed effects (Chamberlain 1980). A Hausman test is employed to identify the most appropriate approach for interpretation, given the assumptions made.2

The quantitative decision is modelled by using linear regressions. Again fixed effects and random effects models are calculated to control for unobserved heterogeneity (Arellano 2003). A Hausman test supports the decision regarding the model adequacy.

The data used for the econometric analysis are derived from the IAB Establishment Panel. These data

---

1 Alternative training motives such as a reputation motive (Sadowski 1980), a stock-keeping motive especially of larger firms (Backes-Geißner 1992) or industry-specific arguments (Büchel/Neubäumer 2001) are not taken into account here.

2 A Hausman test is applied to decide whether the coefficients of a random effects model – which is the default – are biased. In this case fixed effects models are preferred.
are collected annually by means of personal interviews with managers of a randomised sample of firms. In western Germany the first wave of the IAB Establishment Panel was carried out in 1993; since 1996 the sample has also covered eastern Germany. The IAB Establishment Panel is a multiply stratified sample of all German firms which have at least one employee covered by social security (Kölling 2001). The fact that the panel is unbalanced (Bellmann et al. 2002) is ignored in our analysis. The subsample used for this paper does not include firms with fewer than ten employees. Such smaller firms would hardly be able to recruit new apprentices every year.

The endogenous variable in our logit analyses is a dummy which is zero for enterprises which do not recruit an apprentice in a given year and is one if at least one new training contract is concluded. The endogenous variable in the linear regressions is given by the rate of change of the number of new apprenticeship contracts against the previous year.4

In both models we introduce a given set of exogenous variables. The variable “short-term business expectations” uses information which is measured directly. In each panel wave since 1993 firms have been asked to answer the question: “How do you expect the business volume to develop in the current year (t), as compared with the previous year (t-1)? Is it expected to remain constant, to increase or to decrease?” In the case of change, the change in percentage points is asked for. For our analysis we make use of the given raw scores. We assume a positive correlation of the exogenous variable “change in business expectations” with both endogenous training variables. In addition a dummy variable is constructed which has the value of one if the sign of the change in business expectations is negative and this variable interacts with the business expectations.5 The influence of this new variable is expected to be positive.6 This strategy enables us to identify different coefficients depending on the sign of the business expectations (descriptive statistics of the exogenous variables can be found in Tables A1 and A2 in the appendix).

A further set of exogenous variables serves mainly to control for observed heterogeneity of firms. The share of skilled employees among all employees ranges between zero and one and is an indicator of firms’ demand for skilled workers. As we assume, firms recruit at least some of their skilled staff from their apprentices, the correlation between this variable and the training behaviour of the firms should be positive.

The technical state of the firm should influence the training decision in a positive way (Franz et al. 2000). As there is an expected complementarity between human capital and physical capital (Filer et al. 1996), especially firms using the latest technology are limited when recruiting skilled staff on the labour market. Firms with state-of-the-art technology are coded with a value of one whereas firms using obsolete technology are coded with five.

The staff turnover rate as the share of personnel outflow as a percentage of the total number of employees has a serious impact on the investment motive of apprenticeship training. In case the investment motive is decisive for the training decision we assume a negative effect, as firms’ returns from training seem to be limited. Analogously we expect the effect of staff turnover for the quantitative decision.

The share of atypical workers, such as freelancers or agency workers, in the workforce should have a negative influence because enterprises which make considerable use of these groups of workers are expected to recruit know-how from outside. A rate of 100 % is given a value of one.

Collective bargaining often includes negotiations about firm-based apprenticeship training. Firms which are involved in such negotiations are more likely to opt for apprenticeship training and will also recruit more apprentices.

The probability of recruiting at least one apprentice is simply correlated with firm size, measured in

---

3 Following Nijman/Verbeek (1992) unit non response in unbalanced panels should be at random; which is the case with the IAB establishment panel (Hartmann/Kohaut 2000).

4 \[ \text{Rate}_t = N_t - N_{t-1}/N_{t-1} \] with \( N_t \) = number of new apprentices in time t.

5 Alternative models were estimated, including the dummy itself; the results show no significant effect either of the dummy itself or of the interaction term for the OLS model; we therefore use the reduced form here. Analogously we estimated both variants for the logit model. Again, from a qualitative viewpoint, the two models show identical results.

6 As e.g. Ai/Norton (2003) mentioned, the use of interaction terms in nonlinear models such as logit models causes some fundamental problems. In the given case, however, the coefficient for business expectations and the interaction term identifying a negative change should just be interpreted simultaneously. Additional effects result from the control variables. In detail a marginal reduction in business expectations will be compared to the reference situation in the representative firm; the reference situation is defined by business expectations of 0 % and the representative firm by the mean vector of the remaining exogenous variables. Statistical significance of the gross effect of a negative change is to be identified by a simple Wald test; the identification of the standard error using the so-called delta method (see Ai/Norton 2003; Norton et al. 2004; Xu/Long 2005; Oehlert 1992) is not required.
terms of the number of employees; however there are no precise arguments concerning the intensity of apprenticeship training.

Industry dummy variables control for the primary, manufacturing and services sectors. Compared with other sectors the manufacturing industry has a long tradition of apprenticeship training and up to now apprenticeship training has taken place there in very specific training occupations; furthermore training is less school-based and more practical in this field. Finally time dummies are included.

### 3.2 Results of the static analysis

The results of the logit estimates can be found in table 1. The signs for significant coefficients are equal in both the random effects and the fixed effects model. A Hausman test favours the random effects model; so the interpretations are based on this model.

Whereas improvements in business expectations do not have an influence on the probability of recruiting at least one new apprentice, an influence can be seen if business expectations are decreasing. In a representative firm the probability decreases by around 0.3 percentage points if business expectations fall by one percentage point; this effect is highly significant.

The technical state of the firm and the existence of collective bargaining do have the expected positive influence on the training decision. Following the assumption of a complementary relationship between physical and human capital, the training probability increases with the technical state. What is remark-
The determinants of apprenticeship training

Hans Dietrich and Hans-Dieter Gerner

able is the fact that this probability increases if an enterprise changes from the status “there is no collective bargaining” to the status “there is collective bargaining” and vice versa – the marginal effect in the representative firm being four percentage points.

The results confirm a positive correlation between the number of employees and a firm’s training activity. It is more or less plausible that the training probability increases with firm size. The relative entry cost into apprenticeship training decreases as firm size increases.

The share of skilled employees improves a firm’s probability of recruiting new apprentices, and firms in the manufacturing sector are more likely to train apprentices than other firms. Firms with a high staff turnover tend to abstain from concluding new apprenticeship contracts. Finally no significant influence can be found from the share of atypical workers.

Table 2 displays the results of the linear regressions; a Hausman test prefers the fixed effects model. However, the signs of the significant coefficients are again the same in the two estimated models.

An improvement in the business expectations by one percentage point induces an improvement in the vocational training engagement of 0.4 percentage points – an asymmetric behaviour like in the logit models cannot be found. Staff turnover has a decreas-

*** Significant at the 1% level; ** Significant at the 5% level; * Significant at the 10% level. p-values in parentheses.

# It is worth noting that a model was also calculated explicitly with rates of change for every variable. The result of the business expectations remains stable however. On the whole the significance level for the control variables suffers in this case – only the number of employees (the rate of change of the number of employees) remains significant. Moreover there is also no asymmetric behaviour when we exclude all control variables.
ing effect. The share of atypical workers has a signifi-
cant positive influence, which is not in line with our
expectations. Plausible, however, is the positive corre-
lation between a change in the number of employees
and a change in the vocational training engagement.
Moreover the estimations indicate a positive influ-
ence of the share of skilled employees and the exis-
tence of collective bargaining, whereas the coeffi-
cients are supposed to be inconsistent. The weak ex-
planatory power, however, is unsatisfying; both mod-
els only explain about one per cent of the variance.

Altogether it can be concluded that structural deter-
minants obviously do have a greater influence on
the decision as to whether a firm should provide at
least one new apprenticeship than on the extent of
engagement in vocational training. Therefore
changes in the German economy, especially the
change from an industrial to a services economy,
have probably reduced the number of firms which
provide apprenticeships at all. Indications regarding
a cyclical dependence are quite different in the two
approaches. Thus the coefficients for the business
expectations do have the expected signs, at least
when they are significant. In contrast, however, the
fact that an improvement in business expectations
does not influence the probability of opting for new
training at all is surprising. The estimations indicate
that the extent of engagement in training depends
on improvements and also on negative develop-
ments in business expectations. Asymmetric behav-
ior seems to occur in the logit case only. One possi-
ble reason for this result is the fact that until now
we have ignored possible dynamic aspects, which are
quite plausible because reaction takes time. This
consideration is the subject of the next section.

4 Econometric analysis – Part 2:
dynamic approach

4.1 Econometric model, data and
variables

In this section we model explicitly dynamic aspects
by estimating an “autoregressive distributed lag
(ADL model” with fixed effects. In our strategy we
follow Sheldon (2003). Adapting the model to our
question we use as explanatory variables not only
the business expectations in \( t \) but also the business
expectations lagged for several periods and the
lagged information on new apprenticeship contracts.
Fixed effects control for additional firm-specific fac-
tors influencing the training decision such as the
qualification level of the firm’s workforce, the indus-
try of the enterprise or firm size. It should be noted
that Sheldon (2003) estimated an error correction
model (EC), but due to the fact that these two ap-
proaches (ADL and EC) are structurally identical,
the method to control for unobserved heterogeneity
by ordinary within transformation can be applied to
ADL directly.\(^7\)

If the residuals in an ADL model are independent
and identically distributed (iid) and there is not a
unit root in the variables, an OLS model usually
leads to consistent parameter estimates (Verbeek
2002; Beck 2005). In particular serially correlated er-
rors cause serious problems in this context (Beck
2005; Wolters 2003; Baltagi 1998). To avoid this
problem we choose the appropriate lag structure,
based on a Breusch-Godfrey test. Another problem
could, however, arise from the fact that the within
transformation induces another endogeneity prob-
lem in a dynamic model by construction (Greene
2003). As our model selection is based on a Breusch-
Godfrey test, the resulting inconsistency problem
should be small.\(^8\)

Following Carruth/Dickerson (2003), we define a
dummy variable and include an interaction term be-
tween this dummy and the exogenous and endoge-
nous variables in our estimates (the dummy has the
value of one if business expectations are negative)
to model a possible asymmetry.

Box 1 illustrates the model selection process in a
simplified form. The application of this procedure
suggests the following model:

\[
y_{i,t} = \alpha_i + \Theta_1 y_{i,t-1} + \Theta_2 y_{i,t-2} + \Theta_3 \delta_{i,t-1} \delta_{i,t-2} y_{i,t-2} + \Theta_4 y_{i,t-3} + \phi_1 x_{i,t} + \phi_2 x_{i,t-2} + \lambda_i + \epsilon_{i,t}
\]

With:

- \( \alpha_i \): Firm-specific effect (fixed effect)
- \( y_{i,t} \): Rate of change of the number of new
  apprenticeship contracts against the
  previous year, firm \( i \) in year \( t \)
- \( x_{i,t} \): Business expectations, firm \( i \) in year \( t \)
- \( \delta_{i,t} \): Dummy which has the value of one if
  the sign of the business expectations is
  negative, firm \( i \) in year \( t \)
- \( \lambda_i \): Time-specific effect
- \( \epsilon_{i,t} \): Error term.

\(^7\) It would also be plausible to use a vector autoregressive model
with fixed effects. As the endogeneity or causality is clear, how-
ever, we preferred ADL (Hsiao 2004; Verbeek 2002). Up to now
dynamic panel models controlling for selectivity are not common;
besides a lack of implemented standard statistics programmes,
the main argument for not including selectivity in the models is
the extent of complexity.

\(^8\) Another indication in this direction is the fact that the differ-
ence between the coefficients of the business expectations in \( t \) is
not statistically significant in the static and the dynamic models,
which will be discussed later.
Our approach opens up the opportunity to identify differences in firms’ adjustment behaviour depending on whether business expectations are good or bad for just one period or for a longer time. Moreover it is possible to see asymmetries in the adjustment behaviour of the firms. One central assumption is that a firm immediately changes its adjustment scheme if the sign of business expectations changes. What is quite interesting is the result that Wald tests do not find a significant influence of the interaction term between the dummy and the exogenous variable, which is in line with the results in the static case.

The estimates are again based on the IAB Establishment Panel. The exogenous variable is again business expectations compared with the activity a year earlier. As in the static model, the endogenous variable is the change in the number of new apprenticeship contracts compared with the previous year – we take the rate of change. Again we only take firms into account which have at least ten employees; the fact that the IAB Establishment Panel is “unbalanced” is also ignored.

### 4.2 Results of the dynamic analysis

The results can be found in Table 3. As mentioned above, firms’ responses to business expectations are symmetrical with respect to the direction if we look at the short run – in the case of a positive (negative) change in business expectations of one percentage point, the engagement in vocational training increases (decreases) by 0.35 percentage points. It should be mentioned that the result is really in line with those obtained in the static case, the difference is statistically insignificant. In the case that the sign of business expectations does not vary for a longer time (for at least three periods) firms choose a lower equilibrium rate of change in the negative case, although the asymmetry is not really significant (0.21 percentage points in the positive case to 0.185 in the negative case). Finally the strong quantitative correlation between the exogenous and the endogenous variables is quite interesting. This indicates a strong cyclical dependence of the supply of apprenticeships.

One possible economic explanation for the identified (weak) asymmetry could be the fact that firms, irrespective of cyclical factors, train something like a supplement amount, which is not “touched” in the

---

**Box 1**

**Simplified illustration of the model-selecting process**

1) First Step:
   ADL(3.3) model without asymmetric behaviour – selection is based on a Breusch-Godfrey test

2) Second Step:
   Introducing interaction terms of the endogenous and the exogenous variables with the dummy, which has the value of one if business expectations have a negative sign

   \[
   \begin{align*}
   &\delta_1 x_{i,1}, \quad \delta_2 x_{i,2}, \quad \delta_3 x_{i,3}, \\
   &\delta_4 x_{i,4}, \quad \delta_5 x_{i,5}, \quad \delta_6 x_{i,6}, \\
   &\delta_7 x_{i,7}, \quad \delta_8 x_{i,8}, \quad \delta_9 x_{i,9}.
   \end{align*}
   \]

3) Third Step:
   Wald tests to exclude regressors (to take into account considerations regarding efficiency)

4) Fourth Step:
   Breusch-Godfrey test

case of short-term decreases in business expectations. Such an explanation could be justified with the theory of internal labour markets (Saint-Paul 1996; Doeringer/Piore 1971).

5 Application of the estimates

Increasing uncertainty regarding the economic future has been mentioned recently by various authors as being an influential factor for a decreasing commitment of firms to training apprentices (Bellmann/Hartung 2005; DIHK 2006). Within this paper increasing uncertainty is defined as an increase in the changes of the sign of business expectations, whilst the mean of the individual firms’ business expectations remains constant. This definition is in line with the risk concept of Rothschild/Stiglitz (1970), which defines an increase in risk as a “mean preserving spread”. Moreover, it should be mentioned that, strictly speaking, uncertainty and risk are two different concepts, but it is usual to ignore this difference if this distinction is not the subject of the paper (Miller 2002).

Taking a look at the estimates regarding the probability of providing training, business expectations only induce firms to change from the status “new apprenticeships” to “no new apprenticeships”. Uncertainty as defined above would obviously lead to a reduction in the number of firms which provide training.

Finally both the static and the dynamic models indicate that there is no asymmetry in firms’ behaviour as regards adjustment to business expectations in the short run. Thus a negative reaction regarding engagement in vocational training, induced by poor business expectations, reduces the basis (the level of the engagement) so considerably that a subsequent symmetric positive reaction induced by good business expectations would be not strong enough to compensate for the reduction. In the long run however, the dynamic estimates give an indication that negative reactions are less sensitive, but it is clearly doubtful that it makes sense to simulate increasing uncertainty by some long-run changes in the sign of the business expectations (which means the sign does not change until the rate of change of the engagement in vocational training is in equilibrium), if it is taken into account that in the model context long term means around six years and the estimations are based on only seven years. Moreover some long-run changes in the sign of business expectations are usually not recognised as increasing uncertainty but more or less as changes in profit expectations.

Hence the conclusion seems to be justified that increasing uncertainty regarding future prospects, for example business expectations, could be a reason for the decreasing amount of apprenticeship arrangements.

6 Conclusions and further options

The econometric estimations based on the IAB Establishment Panel data provide some evidence that firms respond sensitively to changes in short-term business expectations and adapt their training behaviour correspondingly. These findings correspond with a strong interrelation between training behaviour and the business cycle.

In a short-term perspective, a decrease in business expectations affects the net cost assumptions of firms’ training decisions. From a perspective oriented towards long-term investment, a decrease in business expectations affects the assumptions on future transaction and opportunity costs.

The empirical findings provide some evidence that the sectoral change from the manufacturing industry to the services industry explains some of the reduction in the supply of apprenticeship places, as the density of apprenticeship places in the manufacturing sector is higher than in the services sector.

Furthermore there is some empirical evidence that firms’ departure from collective wage agreements (see Schnabel 2003) reduces both the decision to provide training and the number of training places. But more research is needed to decide whether the two decisions are interrelated or not.

As assumed, the logit model provides some empirical evidence of asymmetric behaviour of firms; these findings correspond with our assumptions on the loss-averse behaviour of firms. Again alternative hypotheses have still to be tested: the costs of entry into apprenticeship training are higher than exit costs. How does this cost asymmetry affect firms’ training behaviour? It is surprising, however, that in the static model the decision to provide apprenticeship training seems to be independent of business
expectations, in contrast to the decision against providing apprenticeship training.

According to our assumptions, firms’ adjustment of their training capacities is positively correlated with the direction of the change in business expectations. However, there is no empirical evidence for the expected asymmetric adjustment behaviour in the static model and an inverse, but weak correlation in the dynamic model.

The empirical findings are in line with our assumptions about the correlation between increasing uncertainty regarding business expectations and the training behaviour. What needs to be done is to implement our assumptions directly in the econometric modelling.

With respect to these limitations, however, it was possible to show that our empirical results concerning the firms’ fundamental training decisions (whether or not to be a training firm and the number of training places) support both our structural explanation and our assumptions on the relevance of business expectations and their change over time on these training decisions. Finally our results correspond with theoretical assumptions on uncertainty.

The formation of individual firms’ business expectations by a given uncertainty over time seems, so far, to be an underestimated explanation but a relevant factor in firms’ contribution to human capital formation.
